

Theory of tunnelling into a multi-band superconductor: decoherence and interference

Da Wang, Yuan Wan and Qiang-Hua Wang*

National Laboratory of Solid State Microstructures and Department of Physics, Nanjing University, Nanjing 210093, China

By an exact formulation of tunnelling into a multi-band superconductor in terms of Green's functions, we demonstrate that the multi-band feature of the iron-based superconductors can lead to novel interference between Andreev reflections and decoherence effect of quasi-particles to Andreev reflections in a tunnelling junction. These effects depend on the relative sign of the gaps for s-wave pairing, and the sign of the Fermi velocities also matters for tunnelling along the nodal direction of d-wave gaps. Experimental probe of such effects could determine both the pairing symmetry and the relative sign of the gaps on different bands.

Introduction: The discovery of iron-arsenide high- T_c superconductors[1] raises a new tide in the research of superconductivity.[2] The immediate theoretical question to ask is what is the pairing symmetry, for which a group-theoretical analysis has been a first guide.[3] As for the pairing mechanism, a plausible scenario is that the strong spin fluctuations at wave vectors connecting the hole-like Fermi pockets near the Γ -point and the electron-like pockets near the M-pockets centered at the corner of the reduced Brillouine zone (BZ) can lead to repulsive pair scattering interactions between the two sets of pockets, and therefore trigger a minus relative sign between gaps on the two sets of pockets.[4] The relative sign between the gaps is therefore a crucial factor to verify/falsify such scenarios. As for intra-pocket pairing symmetry, the situation is in hot debate. Angle-resoled photo-emission (ARPES) measurements find a more or less isotropic gap on each pocket, lending support to s-wave pairing.[5] Nuclear magnetic resonance (NMR)[6] and penetration depth measurements[7] see indications of nodes in the gap function, implying d-wave pairing. This is also supported by some specific heat measurements.[8] However, more recent NMR and penetration depth experiments seem to favor node-less pairing.[9] In any case the relative sign is unknown. Tunnelling experiments provide signatures of both s-wave and d-wave pairing.[10] This may be attributed to the sample quality, but we shall demonstrate that the interpretation of the tunnelling data requires extra care due to the underlying multi-band feature. The crucial idea is that tunnelling into a multi-band superconductor causes interference between the bands, an analogue of the well-known effect in multi-lead mesoscopic systems. Such an effect may encode the relative sign between the gaps, but is absent in, or only partially captured by existing theories of tunnelling.[11] Given the complex experimental situation, a theory that captures the multi-band effect *exactly* in tunnelling is emergently called for.

In the following we first sketch an exact formulation of tunnelling into a multi-band superconductor in terms of boundary Green's functions on the leads, which we derive for practical cases. We then discuss the tunnelling behavior in junctions involving iron-based superconductors

FIG. 1: Schematic plot of the junction involving a superconducting L-lead, a scattering region and a normal R-lead. Here n is the tunnelling direction, x and y are the basis vectors in the BZ, and θ is the angle between a Fermi vector and n . The four pieces of the M-pocket at the BZ corners can be recombined as a closed circle centered at one of the corners.

tors with all of the four Fermi pockets. We demonstrate that the multi-bands lead to novel destructive interference between Andreev reflections and decoherence effect of quasi-particles to Andreev reflections (both involving different bands). These effects depend on the relative sign of the gaps for s-wave pairing, and the sign of the Fermi velocities also matters for tunnelling along the nodal direction of d-wave gaps. Experimental probe of such effects could therefore determine both the pairing symmetry and the relative sign of the gaps on different bands.

Exact formulation: Suppose we are dealing with an N-S junction with a superconductor carrying multi-bands on the left-hand lead (L), a normal metal on the right-hand lead (R), and a scattering center that couples to the α -band of the leads with amplitudes t_α . The junction geometry is illustrated in Fig.1. In our case $\alpha = \Gamma_{1,2}, M_{1,2}$ on the L-lead and $\alpha = N$ on the R-lead. The tunnelling current at bias voltage V can be written as,[12]

$$I = \frac{e}{h} \int d\omega \text{Tr} G_c^r \Gamma^L G_c^a \Gamma^R \sigma_3 [f(\omega\sigma_0) - f(\omega\sigma_0 - eV\sigma_3)] + \frac{2e}{h} \int d\omega G_{c,12}^r \Gamma_{22}^R G_{c,21}^a \Gamma_{11}^R [f(\omega + eV) - f(\omega - eV)] \quad (1)$$

where $G_c^{r(a)}$ is the retarded (advanced) Green's function on the scattering center, $\Gamma^m = -i(\Sigma^{m,a} - \Sigma^{m,r})$ with

$\Sigma^m = \sum_{\alpha} (t_{\alpha}^m)^2 \sigma_3 G_{\alpha}^m \sigma_3$ (for $m = L, R$ and applied separately for the retarded and advanced cases) as the self energy correction to the scattering center due to coupling to the leads so that $G_c^{-1} = z\sigma_0 - \sum_m \Sigma^m$. Here σ 's are Pauli matrices in the Nambu space, and the doubly-numbered subscripts in Eq.(1) refer to the matrix elements. Moreover, G_{α} is the Green's function in the α -band at the open boundary before attaching the scattering center. The first term in Eq.(1) describes quasi-particle contribution, while the second is due to Andreev reflection which is nonzero if Σ^L contains off-diagonal components. Throughout this work $z = \omega \pm i0^+$ for retarded/advanced Green's functions, which is left implicit for notational convenience.

Eq.(1) can be reached by intuitive arguments along the line of Blonder-Tinkham-Kapwijk (BTK).[13] The matrix $T = G_c^r \Gamma^L G_c^a \Gamma^R$ describes the transmission probability [12] for particles/holes from R- to L-lead. For electron transmission, the probability flux is $T_{11}v$, with v the group velocity. Multiplied by the number of modes $dp/2\pi\hbar$ within a momentum interval dp , the total flux is $T_{11}vdp/h = T_{11}d\omega/h$ within an energy interval $d\omega$. In equilibrium this must balance the counter flux from L to R. Under a bias voltage, an electric current arises as $d\omega(e/h)T_{11}[f(\omega) - f(\omega - eV)]$. Similarly, the hole transmission contributes a current $d\omega(-e/h)T_{22}[f(\omega) - f(\omega + eV)]$, where $-e$ accounts for the positive charge. The off-diagonal parts of T describes incoming electrons/holes from R transmitted as outgoing holes/electrons on L. This does not contribute to current, and in fact cancels out due to charge conservation. On the other hand, one can take the Nambu components as generalized channels, by which pairing is nothing but channel hybridization. On the R-lead, such inter-channel transmission is exactly the Andreev reflection. In the spirit of T , the probability reads $A = G_{c,12}^r \Gamma_{22}^R G_{c,21}^a \Gamma_{11}^R$. This contributes an electric current $d\omega(2e/h)Af(\omega - eV)$, where the factor of 2 accounts for the charge $2e$ transported to L during each Andreev reflection. Similarly, for incoming holes reflected as outgoing electrons, the electric current is $d\omega(-2e/h)Af(\omega + eV)$. Collecting everything and integrating over ω we arrive at Eq.(1).

We emphasize that at this stage the formulation is exact, and all possible interference effects in our case are exactly reflected in the self-energies that combines the contributions from all bands coherently. To apply the theory we need the boundary Green's function, the derivation of which is sketched as follows.

Boundary Green's functions: Consider an arbitrary band in a semi-infinite system with a boundary normal $\hat{n} = (\cos\theta_n, \sin\theta_n)$ relative to the x direction of the BZ (the iron-arsenide-iron direction), as illustrated in Fig.1. We assume circular Fermi surface, and near the Fermi momenta we fix the conserved transverse component $K_{||} = K_f \sin\theta$, where θ is the angle between $\mathbf{K}_f$ and $\hat{n}$. For the M-pockets, $Q_{||}$, the transverse projection

of $\mathbf{Q} = (\pi, \pi)$, should be added. We then map the longitudinal degrees of freedom (near the Fermi angles θ and $\pi - \theta$) to a semi-infinite one-dimensional system described by the Andreev equations,[13] demanding that the wave function vanishes a unit distance (the lattice constant, for example) beyond the boundary. These eigen functions and energies are then used to construct the Green's function in a standard manner. Another approach is the T-matrix theory for an infinite plane with an infinite barrier along a line.[14] We get the same results using both approaches under the quasi-classical approximation.

For the s-wave case, the result is independent of $\hat{n}$: $G(\theta) \sim -\mathcal{N}J(\theta)\Psi(\Delta)$ where $\mathcal{N} = K_f/2\pi|v_f|$ is the normal state density of states (DOS) with v_f the Fermi velocity, $J(\theta) = 2\pi \sin^2(K_f \cos\theta)/|K_f \cos\theta|$ is a Friedel-like factor due to the open boundary, and $\Psi(\Delta) = (z\sigma_0 + \Delta\sigma_1)/\sqrt{\Delta^2 - z^2}$, in which $\sqrt{\Delta^2 - z^2} = \sqrt{\Delta^2 - \omega^2}\theta(\Delta^2 - \omega^2) \mp i\text{sign}(\omega)\sqrt{\omega^2 - \Delta^2}\theta(\omega^2 - \Delta^2)$ (for retarded/advanced cases) in practice. Here $\theta(x)$ is the step function.

For the d-wave case, we consider only two practical cases: If $\hat{n}$ is along the anti-nodal direction, $\Delta_{\theta} = \Delta \cos 2\theta$, and we find $G(\theta) \sim -\mathcal{N}J(\theta)\Psi(\Delta_{\theta})$ similar to the s-wave case, except for the θ -dependence in the pairing function.

In contrast, if $\hat{n}$ is along the nodal direction, $\Delta_{\theta} = \Delta \sin 2\theta$, and we find $G(\theta) \sim \mathcal{N}J(\theta)\Phi(\Delta_{\theta})$ with $\Phi(\Delta) = (\sqrt{\Delta^2 - z^2}\sigma_0 - \Delta\text{sign}(v_f)\sigma_2)/z$, where $\text{sign}(v_f) = \pm 1$ if v_f is outward (inward) to the center of the Fermi pocket. The pole at $\omega = 0$ is a particle-hole mixing bound state due to the nodal boundary.[15] Notice that the off-diagonal component in Φ depends on both the sign of the gap and the electron/hole nature of the Fermi pocket, leading to interesting consequence for interference in the Andreev reflection to be discussed. Finally the Green's function in the normal lead can be obtained by simply set $\Delta = 0$.

The above results are applied separately for G in each band, which is then substituted into Eq.(1) for the conductance calculation.

Application to junctions with iron-based superconductors: We define $\gamma_{\alpha} = \mathcal{N}_{\alpha}t_{\alpha}^2$ for the four bands $\alpha = \Gamma_{1,2}, M_{1,2}$ on the L-side and for $\alpha = N$ on the normal R-side, with K_{α} the Fermi radius of the α -pocket. To simplify the discussion we assume $K_{\alpha} = K_f = \pi/2$ for all bands on the L-lead, and set $\gamma_N = \gamma$ and $\gamma_{\alpha=\Gamma_i, M_i} = \kappa\gamma/4$ for a range of values of κ ($\kappa = 1/0$ corresponds to the transparent/tunnelling limit). We also set γ as the unit of energy. For the gap amplitudes on the four pockets we set $|\Delta_{\Gamma_1, M_1}| = \Delta_1$ and $|\Delta_{\Gamma_2, M_2}| = \Delta_2$, with $\Delta_1 = \Delta_{\max}$ and $\Delta_2 = 0.6\Delta_{\max}$ in line with existing experiments. We assume that the gaps on the Γ -pockets are in-phase, so are those on the M -pockets, but the relative sign $\nu = \pm 1$ between the Γ - and M -pockets is left free for discussion.

We consider wide junctions, for which the conduc-

tance $\sigma_\theta(\omega) = dI_\theta/dV$ is calculated by Eq.(1) (in the zero temperature limit) for each conserved transverse momentum $K_{||} = K_f \sin \theta$ (in which $Q_{||}$ should be added for the M-pockets). The channels unmatched by $K_{||}$ should be shutoff. The total conductance is then given by $\sigma(\omega) = \int_{-\pi/2}^{\pi/2} \sigma_\theta(\omega) K_f \cos \theta d\theta / 2\pi$ per unit area.

We first consider tunnelling along $\hat{n} = (1, 1)/\sqrt{2}$. Here $Q_{||} = 0$, and $K_{||}$ can be matched to all Fermi surfaces under our assumption, because of which we expect novel effects. For the s-wave case, by using G_α derived above and under the given assumptions, we get $\Sigma^L(\theta) = -\kappa\gamma J(\theta) \sum_{i=1,2} (z\sigma_0 - \Delta_i \sigma_1 \delta_{\nu,1}) / 2\sqrt{\Delta_i^2 - z^2}$. a) In the in-phase case $\nu = 1$, the σ_1 -component in Σ^L is left intact, and we expect Andreev contribution. However, quasiparticles at $|\omega| > \Delta_2$ acts as dissipative source for (and therefore reduce) the Andreev reflections associated with the larger gap. This is a *decoherence effect*, and is seen as the dips in Fig.2(a) at energies in between the two gap edges. b) In the anti-phase case $\nu = -1$, the off-diagonal component cancels out in Σ^L and consequently in G_c . According to Eq.(1) the Andreev contribution disappears. This is exactly the anticipated *destructive interference effect* among Cooper pairs transported to the L-side during Andreev reflections on the R-side. Within the smaller gap Δ_2 there are no quasi-particles either so that the conductance is completely zero at any level of transparency. This behavior is shown in Fig.2(b). For $|\omega| > \Delta_2$, quasi-particles from Γ_2 - and M_2 -bands start to contribute. Of course, both effects becomes less significant in the tunnelling limit $\kappa \rightarrow 0$ where quasi-particles dominate.

For the d_{xy} -wave case (1,1) is the antinodal direction. According to the previous derivation of G , the structure of Σ^L is similar to that in the s-wave case, except that Δ_i should be replaced by $\Delta_i \cos 2\theta$. The decoherence effect for $\nu = 1$ in Fig.3(a) is less visible because of the size variation in the d-wave gap function. However, the destructive interference effect for $\nu = -1$ in Fig.3(b) is still obvious at $\kappa \sim 1$.

For the $d_{x^2-y^2}$ -wave case, (1,1) is the nodal direction. Here the structure of Σ^L is very different, $\Sigma^L(\theta) = \kappa\gamma J(\theta) \sum_{i=1,2} [\sqrt{\Delta_i(\theta)^2 - z^2} \sigma_0 + \Delta_i(\theta) \sigma_2 \delta_{-\nu,1}] / 2z$, where $\Delta_i(\theta) = \Delta_i \sin(2\theta)$. The extra minus sign before ν comes from the fact that the relative sign of the Fermi velocities is minus for the Γ - and M -pockets. Therefore we expect destructive interference for $\nu = 1$ instead of $\nu = -1$. a) The result for $\nu = -1$ is presented in Fig.3(c). For $\kappa = 1$ the conductance is similar to the corresponding line in Fig.2(a). With decreasing κ , a central peak shows up and we checked numerically that the Andreev contribution dominates, due to the fact that the bound state is a particle-hole mixture. b) For $\nu = 1$, the off-diagonal component cancels out in Σ^L , and the results are shown in Fig.3(d). For $\kappa = 1$ the conductance is of broad V-shape. The normal (i.e., in the

FIG. 2: Conductance (normalized by the normal state σ_n) versus the bias energy $\omega = eV$ for tunnelling along the (1,1)-direction. The relative sign between the s-wave gaps is $\nu = \pm 1$ in (a) and (b) respectively. In each panel $\kappa = 1, 0.9, \dots, 0.1$ from top to bottom, and the curves are vertically shifted for clarity (which approach unity on both sides of ω otherwise).

FIG. 3: The same plot as Fig.2, but for the d-wave case if the tunnelling direction (1,1) is along the antinodal direction for (a) and (b), and the nodal direction for (c) and (d).

absence of particle-hole mixing off-diagonal component) bound-state does not show up here because it has zero group velocity. In the tunnelling limit $\kappa \rightarrow 0$, the normal bound state eventually shows up as a central peak, since in this limit the DOS on the L-lead is measured. In addition, no coherence peak occur in (c) and (d) even in the tunnelling limit, due to the fact that no singularity arise at the gap edge in Φ . The absence of coherence peaks was possibly observed.[10]

For tunnelling along $\hat{n} = (1, 0)$, the two sets of pockets match that of the normal lead at different momenta, so that the Γ - and M -pockets can be treated independently. Since within each set of bands the two gaps are in-phase,

the effect of multi-gaps can be traced in the previous discussion.

We add without going into details that in-plane point-contact on wide boundary is also helpful. Here one simply averages the Green's function over θ first to get the on-site Green's function, which is then substituted into Eq.(1). There is no momentum matching constrain. We see that the off-diagonal part of G survives for the s-wave case and the d-wave anti-nodal tunnelling case, in which both interference and decoherence effect can occur. In the case of d-wave nodal tunnelling, the off-diagonal part cancels out. Furthermore, even out-of-plane tunnelling is useful. Here one simply use the on-site Green's function in an infinite plane: $G_\alpha = -\pi\mathcal{N}_\alpha[z\sigma_0 + \Delta_\alpha(\theta)\sigma_1]/\sqrt{\Delta_\alpha(\theta)^2 - z^2}_\theta$. For s-wave gaps, the off-diagonal part still survives and interference/decoherence occurs, while it cancels out by symmetry for all kinds of d-wave gaps and only quasi-particles contribute to the conductance.

We remark that in the real system, the sizes of the four Fermi pockets differ slightly. The coupling between the scattering center and each band may also differ. These factors may weaken the effects discussed so far, but should still be discernable.

Conclusions: We presented an exact formulation of tunnelling into a multi-band superconductor, and derived the relevant boundary Green's functions. Applying to iron-based superconductors we demonstrate that the multi-band feature can lead to novel destructive interference between Andreev reflections and decoherence effect of quasi-particles to Andreev reflections (both involving different bands) in a tunnelling junction. These effects depend on the relative sign of the gaps for s-wave pairing, and the sign of the Fermi velocities also matters for tunnelling along the nodal direction of d-wave gaps. We propose that in-plane wide junction and point-contact junction, as well as out-of-plane contact junction can be used to probe such effects, and therefore provide decisive information on the pairing symmetry and the relative sign of the gaps on the various bands.

While finalizing this work, we become aware of some recent interesting theories.[16]

Discussion with Bai-Geng Wang is highly appreciated.
